AN1731

VPW J1850 Multiplexing and Motorola's Byte Data Link Controller (BDLC) Module

By Kim Sparks
Systems Engineering
Austin, Texas

Introduction

This application note primarily is intended to teach people about variable pulse width (VPW) J1850 multiplexing and Motorola's byte data link controller (BDLC) module.

Application note structure:

- Evolution of multiplexing
- J1850 overview
- VPW J1850
- Message structure
- Motorola's MDLC vs. BDLC
- A closer look at the BDLC
- Example flowcharts, schematic and software program

The example software program demonstrates how to transmit and receive messages, deal with loss of arbitration, filter messages, switch to 4X mode, and perform error checking with the BDLC. The software closely follows the flowcharts shown in the *Byte Data Link Controller*

Reference Manual , Motorola document number BDLCRM/AD. It is recommended that the reference manual be used in conjunction with this application note.

Evolution of Multiplexing

Over the years, there has been an evolution in how communication is handled between electronic devices within automobiles. Traditionally, a wiring harness carried messages throughout the car. But with the dramatic increase in the amount of electronics in a car, the wiring harness grew in complexity, expense, and weight. It soon became a nightmare to install, and its overall reliability declined.

In an effort to alleviate some of the problems created by the growing wiring harness, the automotive manufacturers started installing communication buses that allowed multiple electronic devices to communicate via shared wiring. Not only did this eliminate wires from the wiring harness, but also connectors and duplicate sensors.

The cost savings due to these bus architectures made them immediately popular with the automotive manufacturers, and, consequently, several UART (universal asynchronous receiver transmitter) protocols emerged. Unfortunately, the manufacturers did not standardize on the same multiplexing strategies, which resulted in the automotive suppliers constantly struggling to keep up with the nuances in the technology. It became such a burden that the Society of Automotive Engineers (SAE) decided to standardize the allowable multiplexing networks within automobiles, which resulted in three classes of data communications standards. Each class is designed with specific systems in mind. See [Table 1](#) for details on each class of communication.

Table 1. SAE-Approved Classes of Data Communications

	Class A	Class B	Class C
Speed	Low	Medium	High
Bit timings	< 10 Kbits per second (bps)	10 Kbps to 125 Kbps	125 Kbps to 1+ Mbps
Application	Comfort systems	Non-critical systems	Human-critical systems

Today's cars rely heavily on multiplexing, and the benefits are far reaching. The most apparent benefit is the reduction of hardware. This drives down cost and mechanical failures, but increases the need for more sophisticated software controlling the devices (or nodes) on a bus. Even the slightest software bug can be as catastrophic as a hardware defect. Motorola has addressed this issue by producing microcontrollers with FLASH memory that can be reprogrammed over a multiplex bus. In the future, automotive manufactures will be using both multiplexing technology and FLASH technology to ensure that each node on the bus has the latest revision of software during the entire life of the car.

J1850 Overview

For nodes that need to communicate at medium speeds, the class B data communications network is used. To communicate at this speed, at the present time SAE has approved one bus architecture called J1850, which is an open architecture bus allowing nodes to be added or deleted easily without affecting other nodes. See [Figure 1](#) for a diagram of the typical nodes connected to a J1850 bus.

AUTOMOTIVE MULTIPLEX SYSTEM

Serial data Communications: Allows for all electronic systems to communicate with each other and an external Diagnostic port

Figure 1. J1850 System Example

J1850 is widely accepted in the U.S. automotive world because it is flexible enough to satisfy both simple and complex applications. The architecture is so flexible that during its development two separate messaging protocols emerged:

- Variable pulse width modulation (VPW)
- Pulse width modulation (PWM)

Both of these protocols map to the International Standards Organization's (ISO) Open Systems Interconnection (OSI) model. The ISO organization is responsible for setting the standards for applications that run over a network. Their OSI model is composed of seven layers that networks attempt to conform to. Of these seven layers, VPW and PWM have the same application and data link layers. Since they have the same application layer, they both use the same messages, filtering schemes and diagnostic codes. Conforming to the same data link layer ensures that the addressing strategy, message buffering, arbitration, framing, error detection, and many other aspects of data transmission

are handled the same. (See the SAE J1850 specification for more information on the application and data link layers.)

In the OSI model, VPW and PWM differ in the physical layer. This layer defines the physical methods used to transmit and receive data on a J1850 bus, including wiring, signal types, and bit timings. **Table 2** shows the main differences in the physical layer.

Table 2. Physical Layer Differences Between VPW & PWM J1850

	VPW	PWM
Bit rate	10.4 Kbps	41.6 Kbps
Bit pulse width	Variable	Constant
Media	Single wire	Dual wire

The PWM messaging structure works just like a standard PWM with the level of the signal representing a logic 1 or 0. VPW messaging is quite different. Not only does the state of the bus determine a logic 1 or 0, but also the width of a pulse.

VPW J1850

The physical layer of a VPW J1850 bus is a single wire that can have up to 32 nodes connected to it. This includes any diagnostic equipment that will be connected to the car by the manufacturer or dealer in the future. The maximum length of the bus can be 35 meters within a car, with an additional 5 meters connected externally for diagnostic equipment.

A VPW bus operates in two states:

- **Active** — In the active state, the bus is driven between 6.25 V and 8.00 V.
- **Passive** — In the passive state, the bus is pulled down to between 1.5 V and 0 V.

As each bit of a message is transmitted, there is always a transition between states. Therefore, the message is made up of a series of high,

low, high, low, etc. pulses. Logic 0s and 1s are uniquely encoded into both the active and passive states by varying the width of the pulse. Only two pulse widths are used when encoding data, either a short of 64 μs or a long of 128 μs . [Figure 2](#) shows how 0s and 1s are encoded in the passive and active states.

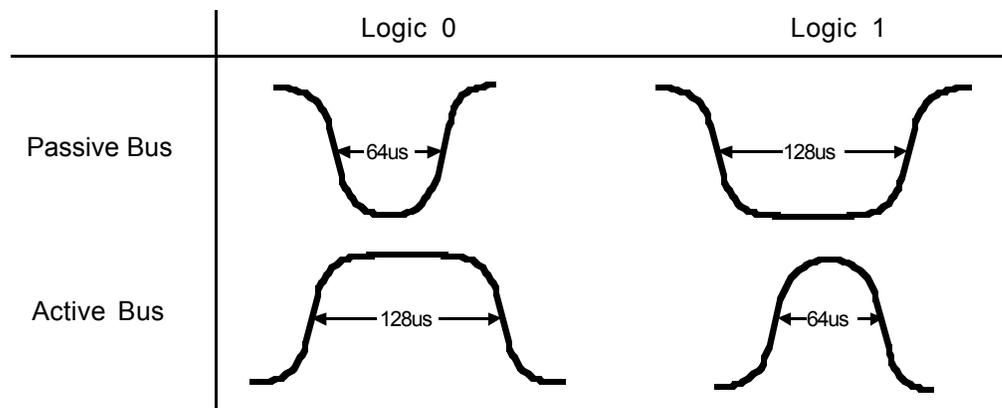

Figure 2. VPW Logic 0 and Logic 1

The 64 μs and 128 μs bit timings are only nominal timings. It doesn't make sense to place strict timing specs on signals that have to travel a considerable distance in a noisy environment. SAE recognized this and placed liberal specifications on the allowable bit timings. [Table 3](#) shows the valid ranges. Notice that the receiver specs are even more tolerant than the transmitter specs. This is understandable, considering most of the noise will be injected while the message is traveling to a node.

Another problem inherent to single wire buses is grounding. With a single wire, it is assumed that all the nodes on the bus are using the exact same ground. If the nodes are at different ground levels, then ground offset problems can result. In this case, the transmitting node sends a message with the correct bit timings and pulse levels according to its ground. But, the receiving node has a different ground, so the bit timings look either slightly longer or shorter than nominal. Usually, this isn't a problem because of the tolerant specs. However, if the difference in ground levels is severe enough, then an invalid symbol error may occur on the bus.

Table 3. VPW Pulse Width Times (μs)

Symbol	Tx, Min	Tx, Nom	Tx, Max	Rx, Min	Rx, Max
Short pulse	≥ 49	64	≤ 79	> 34	≤ 96
Long pulse	≥ 112	128	≤ 145	> 96	≤ 163
SOF/EOD	≥ 182	200	≤ 218	> 163	≤ 239
EOF	≥ 261	280	N/A	> 239	N/A
BRK	≥ 280	300	$\leq 5,000$	> 239	$< 1.0 \text{ s}$
IFS	≥ 280	300	N/A	> 280	N/A

One other issue that should be addressed is how noise emissions are controlled. Since the J1850 messages travel down a single wire bus at 10.4 Kbps, some people will be concerned that noise will be radiated into other systems. After all, a single wire radiates substantially more noise than a twisted pair of wires. This was taken into consideration when the VPW architecture was designed, and it was decided that the signal had to be wave-shaped to meet specific rise and fall times. By smoothing the sharp corners of the waveform, the noise can be effectively reduced. See [Figure 3](#) for an example pulse.

Figure 3. VPW Signal Example Pulse

Message Structure

A legal J1850 message can have several formats. **Figure 4** shows the structure of a full message. The BDLC reference manual contains a more detailed description of each of these fields.

SOF	Header	Data_0	...	Data_N	CRC	EOD	NB	IFR_I	...	IFR_N	EOF	IFS
-----	--------	--------	-----	--------	-----	-----	----	-------	-----	-------	-----	-----

Figure 4. General Message Format

Every message begins with a start-of-frame (SOF) symbol. This is an active pulse that remains high for nominally 200 μ s. Its unique bit timing sets it apart from other symbols on the bus, such that all the nodes will know exactly when a message is starting.

Following the SOF is the header information. Either one byte or three bytes is used for header information. There are two different kinds of 1-byte headers, either the single byte header or the 1-byte consolidated header. The difference between the two is bit 4. For the 1-byte consolidated header, bit 4 must be set to a 1 to signal the receiver that a 1-byte consolidated header is being used, instead of a 3-byte consolidated header. The 3-byte consolidated header consists of a priority/message type byte, target address byte, and source address information byte. **Figure 5** shows the different types of headers approved by SAE.

At this point, realizing the significance of the header byte is important. Since a VPW bus is masterless, meaning that each node has an equal opportunity to transmit a message on an idle bus, there has to be a way to resolve conflicts when multiple nodes try to transmit at the same time. The method SAE has approved is called bit-by-bit arbitration, which is a non-destructive way of allowing the node with the highest priority to win control of the bus. The arbitration process begins with the SOF and usually ends with the header information. As the nodes go through arbitration, they start transmitting simultaneously. An active state always dominates over a passive, or a zero always dominates a one. Therefore, whichever message has a lower value in the header information wins

arbitration. If the nodes are arbitrating with the same header information, then arbitration continues through every byte of the message until one node wins.

Single Byte Header

Bit 7	Bit 6	Bit 5	Bit 4	Bit 3	Bit 2	Bit 1	Bit 0
Message ID (256 bytes)							

1-Byte Form of Consolidated Header

Bit 7	Bit 6	Bit 5	Bit 4	Bit 3	Bit 2	Bit 1	Bit 0
x	x	x	H = 1	x	x	x	x
Message ID (128 bytes)							

3-Byte Form of Consolidated Header

Byte 1	Byte 2	Byte 3
Priority level? IFR required? Functional / physical addressing? Specific message type?	Target address	Source address

Figure 5. SAE-Approved Header Formats

Following the header information are the data bytes. The maximum number of data bytes that SAE allows in a normal J1850 message is 12, which will be transmitted most significant bit (MSB) first. Once all the data is transmitted, a cyclic redundancy check (CRC) byte is calculated and appended to the message. The microcontroller's hardware generates the CRC by feeding the header and data bytes into the polynomial $P(X) = X^8 + X^4 + X^3 + X^2 + 1$. The resulting byte is appended to the outgoing message. On the other end, when the message is received by the receiving node, it shifts the header, data, and CRC bytes through the CRC circuitry. The circuitry performs another polynomial calculation that should produce \$C4 (hex). If it doesn't, then the receiving node should flag the sender that an error has occurred. If the result does equal \$C4 (hex), then it is safe to assume the data received is accurate.

Motorola's MDLC vs. BDLC

Motorola has developed two modules that can communicate on an SAE J1850 10.4- Kbps VPW bus:

- Message data link controller (MDLC)
- Byte data link controller (BDLC)

These names refer to how the module handles transmitting and receiving messages on the bus, either an entire message at a time or a byte at a time. Both modules are designed to perform the critical J1850 protocol requirements automatically, such as automatic transmission synchronization to bus frame slots, calculation/auto-insertion/checking of message CRCs, and checking for symbol/framing errors.

The MDLC was the first integrated J1850 module on an 8-bit microcontroller. It is optimized for messages that require a 3-byte header, CRC, and no IFR. One transmit and two receive buffers are built into the MDLC's hardware. Each buffer is 11 bytes long, which means that only 11 data bytes can be transmitted in a message. However, since there are two receive buffers, a message of any length can be received correctly by the module.

There are several benefits to having built-in buffers like the MDLC. For instance, it makes transmitting and receiving messages easy from a software point of view. When a transmission fails to go out due to a loss of arbitration, the hardware is designed to retransmit the message automatically once the bus is available. Again, this reduces the amount of user code needed. Aside from software savings, the MDLC also affords hardware savings because it has a built-in transceiver.

The next integrated J1850 module that was developed by Motorola is the BDLC. As the name implies, it deals with messages on a byte-by-byte basis, unlike the MDLC which handles entire messages at a time. The BDLC was intended to be a more simplistic MDLC, where the user software has more control over how the node reacts to messages on the bus. One example of this is how filtering is handled by the BDLC. Since the user's software can evaluate each byte as it is being received, the software can determine whether to process or ignore the message. With

this added control comes the price of needing more sophisticated software.

Another benefit of the BDLC is that it supports all the features in the J1850-VPW specification, including the optional ones, such as in-frame response. It has become a popular module and has been integrated on several families of microcontrollers, including the HC05, HC08, and HC12.

Similarities of the MDLC and the BDLC modules include:

- SAE J1850 compatible
- 10.4-Kbps variable pulse width (VPW) modulation format
- Digital noise filter
- Collision detection
- Hardware cyclical redundancy check (CRC) generation and verification
- Two power-saving modes with automatic wake up on network activity
- Polling and CPU interrupts available
- Receive block mode supported

Differences between the MDLC and the BDLC modules include:

- The MDLC cannot transmit in block mode, but the BDLC can.
- The MDLC can co-exist with devices supporting 4X mode, but it ignores all the 4X messages. The BDLC can receive messages in 4X mode, but cannot transmit in that mode.
- The MDLC automatically will try to retransmit a message when it loses arbitration during a transmission. The BDLC will generate an interrupt when the module loses arbitration, but the user's software must take care of retransmitting the message.
- The MDLC does not support in-frame response (IFR). The BDLC supports IFR types 0, 1, 2, and 3.

- The MDLC has a built-in transceiver, whereas an external transceiver must be provided for the BDLC for most parts. The BDLC modules that do not have built-in transceivers have analog and digital loopback modes for debugging the transceiver.

A Closer Look at BDLC

For an in-depth description of the BDLC module, use the *Byte Data Link Controller Reference Manual*. It provides information about the BDLC for any HC05, HC08, and HC12 microcontroller. This section of the application note explains some of the less intuitive features of the BDLC, including:

- How the BDLC is enabled
- When receiver and transmitter circuitry is activated following a reset
- What flags are set in the BDLC state vector register (BSVR) as a result of an error
- How an EOF flag can wake a part from wait mode
- How the digital loopback mode works with stop mode

How the BDLC is Enabled

The BDLC does not have an enable bit like Motorola's SPI (serial peripheral interface) and SCI (serial communications interface) communications modules on microcontrollers. Instead, it is automatically enabled during any type of microcontroller reset.

When Receiver and Transmitter Circuitry is Activated After a Reset

The first thing the BDLC does following a reset is wait until it observes an idle bus for $\sim 280 \mu\text{s}$ or an EOF time period. When it sees this, it enables the receiver circuitry and sets the EOF flag in the BSVR. At this point, the BDLC is ready to receive messages, but first the EOF flag should be cleared by the user's software.

The only situation where the EOF flag will not be set after a reset is if the ignore message bit (IMSG) in BDLC control register 1 (BCR1) is set at

the end of the 280- μ s startup period. With IMMSG bit set, all the BDLC interrupt requests are masked and the status bits in the BSVR are held in their reset state. Even with the EOF flag not being set, the receiver circuitry is still activated.

NOTE: *It is recommended that the IMMSG bit in BCR1 not be cleared by the user's software. The BDLC hardware automatically clears this bit when receiving a message, re-enabling the BDLC interrupts. The IMMSG bit should be set only when the user has determined that the incoming message is of no interest.*

Similarly, the BDLC won't activate the transmitter circuitry until it observes a passive period of 20 μ s on the bus or an inter-frame separator (IFS) time period. Since there isn't an IFS flag in the BSVR, this enable sequence is transparent to the user.

What Flags are Set in the BSVR as a Result of an Error

The BDLC has two error flags:

- CRC error flag
- Invalid symbol or out-of-range error flag

A CRC error occurs when the BDLC shifts an incoming message through its CRC error checking circuitry and the result is not correct. When this happens, the BDLC handles the error like this:

- While the data bytes are being received, the RDRF flag gets set as usual.
- When the erroneous CRC is received, first the RDRF flag is set because the CRC byte is received.
- Then the CRC error flag is set, because the result of the CRC polynomial calculation was not correct. This does not stop the reception of the rest of the message, so the EOD, NB, IFR, EOF, and IFS symbols are received as normal.
- At the end of the message an EOF flag will be set, just like it would be for a good message. At this point, the message is completely received, and the user's code should deal with the bad message appropriately.

- Once all the flags are cleared, the BDLC is ready to continue transmitting and receiving messages.

The invalid symbol or out-of-range error flag is handled slightly differently than the CRC error. This error flag encompasses all errors on the bus outside of the CRC error. Therefore, the user will not be able to determine exactly what caused the invalid symbol error. For this reason, the BDLC will stop transmitting a byte immediately if an error occurs during transmission and will set the invalid symbol flag. Likewise, if the BDLC receives a bad byte, it immediately will discard the incoming byte and set the invalid symbol flag. In this case, the BDLC waits until the bus is idle for an EOF time period (~280 μ s) before receiving any new messages. The BDLC will signal that an EOF time period has expired by setting the EOF flag. After the invalid symbol and EOF flags are cleared, the BDLC is ready to continue communicating on the J1850 bus.

How an EOF Flag Can Wake a Part from Wait Mode

If the part is in wait mode with the internal clocks running, an EOF flag will wake it up. Under most circumstances, this won't happen because the EOF flag is generated only after a message is received, a reset, or an invalid symbol.

NOTE: *Be careful to execute the WAIT instruction after the EOF interrupt after a reset or an invalid symbol.*

How the Digital Loopback Mode Works with Stop Mode

When the digital loopback mode bit (DLOOP) is set in the BDLC control register 2 (BCR2), the transmit and receive pins are tied together internally. This works fine for all scenarios except one: when using digital loopback, stop mode, and an external transceiver that inverts the polarity of the receive pin. When using a transceiver that inverts the receive signal, most users clear the receive pin polarity bit (RXPOL) in the BDLC analog and roundtrip delay register (BARD). That way the receive pin is inverted back to normal orientation internally by the microcontroller.

If the STOP instruction is executed with the above hardware and software set up, then the transmit pin will idle low when not transmitting and the receive pin will see a high. This is because of the internal inverter on the receive pin and the DLOOP is set. When the STOP instruction is

executed with the two opposite polarities on the pins, the BDLC will interpret this as activity on the bus and immediately wake up the part.

The best way to work around this scenario is to put an inverter integrated circuit between the transceiver's RX pin and the microcontroller's BDRxD pin and set the RXPOL bit in the BARD to normal/true polarity.

BDLC Example Software Program

Refer to the BDLC reference manual for generic flowcharts on initializing the BDLC, transmitting messages, receiving messages, and transmitting IFRs.

The program GEN_BDLC in **Appendix A** shows one of the many ways of writing drivers for the BDLC. Its purpose is to demonstrate the main functionality of the BDLC module, including transmitting a message, receiving messages, filtering incoming messages, and dealing with loss of arbitration and various errors. It points out the correct sequence that should be used to program the module and any idiosyncrasies that the user may run into with the BDLC.

The comments in the program explain in detail how it works, but here's a brief description of what it does.

- Immediately after a reset, the message \$55 \$55 \$55 \$55 is loaded into a RAM buffer and is transmitted on the J1850 bus. That's the only transmission that the program performs, but it can be modified easily by loading the RAM buffer with another message and transmitting it.
- As far as receiving messages, the program is designed to receive any message that contains a \$55 in the second byte. It will filter out any message that doesn't meet this requirement. If the message \$6c \$55 \$01 \$04 is received, then the module will switch into 4X receive mode and start receiving messages at 41.6 Kbps.

The most important part of the program is how the BDLC interrupts are handled. For the HC08 Family of microcontrollers, a jump table is used to service the interrupts.

NOTE: *It is strongly recommended that interrupts are used with the BDLC with a jump table to ensure that data isn't lost.*

Figure 6 shows the flowchart of what happens when a BDLC interrupt occurs.

Figure 7 shows the schematic for the hardware set up.

*****
*****          MCU Initialization Subroutine          *****
*****
*****
* This subroutine clears the appropriate RAM variables used by the program,
* and delays for one EOF time period (~280 us). This delay allows the
* BDLC to monitor the bus and enable the receiver circuitry internally
* after it sees the bus idle for an EOF time period. Since the IMSG bit is
* left set until the first SOF is received, there will not be an EOF
* interrupt. When the first SOF is received the IMSG bit is automatically
* cleared by the hardware.
*
* The final step of the microcontroller's initialization is to clear its
* interrupt mask bit.
*****

```
*****
*****                      BDLC Interrupt Service Routine          *****
*****
```

```
*****
* The key to servicing the interrupts generated by the BDLC is to use a
* jump table. The value in the BSVR is used to index to the correct
* location in the jump table. When the BSVR is accessed by the user's
* software, the bit value read reflects only the highest priority
* interrupt. Once that interrupt is cleared, any pending interrupts are set.
*
```

```
* The following is a summary of the actions taken by the each interrupt
* service routine:
```

- * \$00 - No Interrupts Pending. This interrupt service routine should never happen.
- * \$04 - EOF Interrupt. First, the routine checks to see if loss of arbitration occurred. If so, then the message that needs to be retransmitted has already been loaded by the program and the transmit RAM variables should not be cleared, only the receiver variables. Next, the routine checks to see if the EOF was a result of transmitting a message or receiving one. If it was result of transmitting, then the transmitter & receiver RAM variables are cleared. If the EOF was a result of receiving a message, then the received message is analyzed to see if the BDLC should switch into 4x receive mode or not. If so, then it is switched and the receiver RAM variables are cleared. If not, then just the receiver RAM variables are cleared.
- * \$08 - RXIFR Interrupt. IFR is not used in this program, so this interrupt should not happen.
- * \$0C - RDRF Interrupt. This interrupt occurs when a data byte is received. Two things are checked as the bytes are received. First does the second byte = \$55 if not then ignore the rest of the message. Second, does the first 4 bytes of the message = \$6c \$55 \$01 \$04? If so, then switch into 4x receive mode.
- * \$10 - TDRE Interrupt. This routine continues to transmit the message that has been stored in the tx_message buffer. If the last byte has been sent, then an EOD is transmitted.

Application Note

* \$14 - LOA Interrupt. In this routine, the loss of arbitration and retransmit RAM variables are set, and the transmit counter is cleared. That way the message to be transmitted will be loaded and transmitted again.

* \$18 - CRC Error flag. If the CRC error occurred during a transmission then the retransmit RAM variable is set. Also the transmit and receiver RAM variables are cleared. If the CRC error occurred while receiving a message, then only the receiver RAM variables are cleared.

* \$1C - Symbol Invalid Interrupt. Same sequence is used as for a CRC error, except that an EOF delay (~280 us) is added before the software returns from the interrupt service routine. The delay is added because after an invalid symbol interrupt the BDLC module needs to see the bus idle for an EOF time period. This ensures that there isn't still a fault on the bus. An EOF interrupt will be generated once the EOF time period has expired.

* \$20 - Wakeup flag. Low power modes are not being used in this program, so this interrupt should never occur.

Application Note

Motorola reserves the right to make changes without further notice to any products herein. Motorola makes no warranty, representation or guarantee regarding the suitability of its products for any particular purpose, nor does Motorola assume any liability arising out of the application or use of any product or circuit, and specifically disclaims any and all liability, including without limitation consequential or incidental damages. "Typical" parameters which may be provided in Motorola data sheets and/or specifications can and do vary in different applications and actual performance may vary over time. All operating parameters, including "Typicals" must be validated for each customer application by customer's technical experts. Motorola does not convey any license under its patent rights nor the rights of others. Motorola products are not designed, intended, or authorized for use as components in systems intended for surgical implant into the body, or other applications intended to support or sustain life, or for any other application in which the failure of the Motorola product could create a situation where personal injury or death may occur. Should Buyer purchase or use Motorola products for any such unintended or unauthorized application, Buyer shall indemnify and hold Motorola and its officers, employees, subsidiaries, affiliates, and distributors harmless against all claims, costs, damages, and expenses, and reasonable attorney fees arising out of, directly or indirectly, any claim of personal injury or death associated with such unintended or unauthorized use, even if such claim alleges that Motorola was negligent regarding the design or manufacture of the part.
